Abstract
New estimates of the various contributions to the radiative forcing (RF) from aviation are presented, mainly based on results from the TRADEOFF project that update those of the Intergovernmental Panel on Climate Change (IPCC, 1999). The new estimate of the total RF from aviation for 2000 is approximately the same as that of the IPCC’s estimate for 1992. This is mainly a consequence of the strongly reduced RF from contrails, which compensates the increase due to increased traffic from 1992 to 2000. The RF from other aviation-induced cirrus clouds might be as large as the present estimate of the total RF (without cirrus). However, our present knowledge on these aircraft-induced cirrus clouds is too poor to provide a reliable estimate of the associated RF.

Introduction
More than 5 years have passed since the publication of the 1999 IPCC Special Report “Aviation and the Global Atmosphere” (PENNER et al., 1999). In 2003, the European Conference on Aviation, Atmosphere and Climate (AAC) in Friedrichshafen, Germany (SAUSEN et al., 2004) provided an update to our knowledge on this topic. A central outcome of the 1999 IPCC report was an estimate of the radiative forcing (RF) arising from the different aviation-induced perturbations to the atmosphere, e.g., their Figure 6–14. Here we present an update of this figure, which accounts for advances in science.

Note that RF (e.g., SHINE et al., 1990) is considered a metric of climate change (FUGLESTVEDT et al., 2003): for many perturbations of species radiatively active in the atmosphere, in particular for well-mixed greenhouse gases, the radiative forcing RF is proportional to the expected equilibrium climate change in terms of global mean surface temperature change $\Delta T_s$, where $\lambda$ is the climate sensitivity parameter (unit K/(Wm$^{-2}$)). The use of equation (1.1) implicitly assumes that $\lambda$ is independent of the forcing mechanism.
However, it is well documented that $\lambda$ varies by more than a factor of two among models, reflecting, e.g., different parameterisations implemented (e.g., CESS et al., 1990; PRATHER et al., 1999). The proportionality in equation (1.1) forms one of the bases for the Kyoto Protocol and for emissions trading of the gases in the Kyoto “basket”, as RF is one of the terms entering the Global Warming Potential (GWP).

Recent studies (e.g., STUBER et al., 2001; JOSHI et al., 2003; COOK and HIGHWOOD, 2003) have shown that $\lambda$ is not constant for a range of perturbations to radiatively active species, in particular if the additional radiatively active species are inhomogeneously distributed, as is the case for aviation-induced ozone changes. Already PRATHER et al. (1999) pointed out this problem, and this also has implications for including aviation in emissions trading (LEE and SAUSEN, 2000). Despite these caveats we assume that equation (1.1) is approximately valid, and that therefore, calculating aviation RF allows a comparison of aviation-induced climate change with other anthropogenic impacts.

2 IPCC results for 1992

The blue bars in Figure 1 (see also Table 1) display the IPCC aviation RFs for the year 1992 from PRATHER et al. (1999). The most prominent positive contributions (warming) are from $\text{CO}_2$, $\text{O}_3$ and (linear) contrails, which are of approximately the same magnitude ($\sim 20 \text{ mW/m}^2$). A negative contribution (cooling) of similar magnitude results from $\text{CH}_4$ changes ($-14 \text{ mW/m}^2$). Smaller contributions arise from water vapour and the direct (radiative) effects of sulphate and soot aerosols. All these values are “best estimates” that sum up to a total of 48.5 $\text{ mW/m}^2$.

PRATHER et al. (1999) did not provide a best estimate for the aircraft effect on cirrus clouds (beyond linear contrails) due to the very poor knowledge available. But rather a range for the potential best estimates was given (Table 2), i.e., the top of the blue line with the circle at the ends (Figure 1) gives an estimate of the upper limit for the contribution of aviation-induced cirrus changes (40 $\text{ mW/m}^2$). Since a best estimate could not be provided, the total aviation RF did not include the cirrus effect.

Recently, MINNIS et al. (2004) provided another upper estimate (double black lines with circles at the ends in Figure 1) for the aviation-induced cirrus changes (25.5 $\text{ mW/m}^2$). Their estimate is based on additional information that was not available to PRATHER et al. (1999). Note that the MINNIS et al. (2004) estimate includes the contribution from linear contrails, i.e., the MINNIS et al. value is considered an upper estimate of the total aviation induced cloud effects (contrails plus other cirrus clouds).

Except for the total, the whiskers in Figure 1 display the 2/3 confidence intervals of PRATHER et al. (1999), i.e., they provide 2/3 or 67 % probability ranges that are
Table 1: Radiative forcings (RFs) from aviation [mW/m^2]. The best estimates for 1992 by IPCC (1999) and two estimates for 2000 are given: one is derived from IPCC (1999) by linear interpolation, the second is based on the mean values resulting from the TRADEOFF project. As in IPCC (1999), the TRADEOFF RFs for CO2, O3 and CH4 were scaled by a factor of 1.15. The RFs from O3 and CH4 are both a result of aircraft NOx emissions.

meant to be symmetrical about the best estimate. The best estimate is not always the mean of the upper and lower values. The probability that the true value is less than the lower value is 16%, and the probability that it is less than the upper value is 84%. The range between the low and high values is equivalent to the “1-sigma” range of a normal (i.e., Gaussian) probability distribution. The derivation of these confidence intervals lay with the expert judgement of the scientists contributing to IPCC (1999) and included a combination of objective statistical models with subjective expertise. Thus, the 67% confidence intervals do not imply a specific statistical model.

3 An IPCC-based estimate for 2000

PRATHER et al. (1999) also provided estimates of the aviation RF for the year 2015. By linear interpolation of the RF for 1992 and 2015, we calculated the RF for the year 2000 (Table 1). The results are displayed by open bars behind the blue bars in Figure 1. These are the results that PRATHER et al. (1999) would have shown if they had provided numbers for 2000 and are the results that we will compare our new estimates for 2000 with.

4 The TRADEOFF estimate

In TRADEOFF, an EU FP5 research project (2000–2003), several groups worked on new estimates of the radiative forcings from aviation. The red bars in Figure 1 represent the TRADEOFF mean values for the year 2000 (see also Table 1).

Since a detailed emissions inventory was not available for the year 2000, a 1991/92 movements base year was projected, corrected by ICAO statistics through to 2000 and converted into emissions, fuel burn and distance travelled. The total fuel burn (civil and military) was 169 Tg per year and the NOx emissions 2.16 Tg NOx (as NO2) per year. These calculations are in good agreement with the estimate for 2000 used in the Third IPCC Assessment Report (IPCC, 2001). A more detailed inventory has recently become available from the EU FP5 project AERO2K. As in PRATHER et al. (1999), the RFs from CO2, O3 and CH4 were scaled by a factor of 1.15 in order to account for extra fuel burn, which results from imperfect routing, sub-optimal cruise altitude, holdings, etc.

The RF from aviation CO2 (22 mW/m^2, scaled to 25 mW/m^2) does not differ from the IPCC-based estimate for 2000. The fuel burn grew somewhat faster than estimated by IPCC (1999). However, this is compensated by a slightly smaller RF per unit CO2 increase (IPCC, 2001).

In order to determine the RF from aircraft-induced O3 increase and CH4 loss, the perturbations to the abundance of these species resulting from aviation NOx emissions were calculated with five new-generation Chemical Transport Models (CTMs) and Climate-Chemistry Models (CCMs): TOMCAT (University of Cambridge: LAW et al., 2000; KÖHLER, 2003), CTM-2 (University of Oslo: KRAABOL et al., 2002; GAUSS et al., 2003a, 2003b), ECHAM4.L39(DLR)/CHEM (DLR: HEIN et al., 2001; GREWE et al., 2002), LMDz-INCA (LSCE: HAUGLUSTAINE et al., 2004) and ULAQ (University of L’Aquila: PITARI et al., 2002). The models listed above have been evaluated by BRUNNER et al. (2003, 2005). While the aircraft-induced O3 perturbation was directly simulated, the CH4 change was estimated from a change
in CH4 lifetime (BERNTSEN et al., 2004) resulting from an OH change in analogy to the method applied by e.g., DERWENT et al. (1999) or ISAKSEN et al. (1999). Finally, the radiative forcings from these perturbations were calculated using off-line radiative transfer codes, yielding forcings in the range 12–28 mW/m2. (The range results mainly from different ozone perturbations.) The average value is 19 mW/m2 (scaled to 22 mW/m2), which we take as our best estimate. This is somewhat smaller than the IPCC-based estimate for 2000; however, in the light of the large 2/3 confidence interval this difference is not significant. The corresponding RF from aircraft-induced CH4 loss (mean: –9 mW/m2, scaled to –10 mW/m2) is only about half the IPCC-based estimate. The new value still is within the 2/3 confidence interval of PRATHER et al. (1999). Current estimates of O3 and CH4 lifetime perturbations from aircraft emissions give somewhat smaller values than those reported in the IPCC (1999) study. Furthermore, the number of models participating in TRADEOFF was smaller than the number of models contributing to PRATHER et al. (1999). This may explain some of the discrepancy between the IPCC (PRATHER et al., 1999) and the TRADEOFF results.

The changes to the RFs from water vapour, direct sulphate and direct soot are minor and will therefore not be discussed further.

The biggest change from the IPCC results (see also MINNIS et al., 1999) is the RF from (linear) contrails, which has been calculated to be about 10 mW/m2 (6 mW/m2 scaled from MARQUART et al. (2003), who calculated 3.5 and 9.8 mW/m2 for the years 1992 and 2015, resp.; 15 mW/m2 scaled from MYHRE and STORDAL (2001), who calculated 9 mW/m2 for the year 1992). It is approximately a factor of three to four smaller than the IPCC-based estimate (Table 1). The new estimate of MARQUART et al. (2003) is based on more observations of contrails (e.g., MEYER et al., 2002), refined parameterisations of contrail coverage and contrail microphysical properties (e.g., PONATER et al., 2002; MARQUART and MAYER, 2002), and takes the temporal and spatial variation of the background atmosphere into account. The estimate of MYHRE and STORDAL (2001) would be somewhat lower than the estimated 15 mW/m2 if lower contrail cover and optical depth were included, but is still likely to be larger than the estimate of MARQUART et al. (2003). The new best estimate is just at the lower edge of the IPCC 2/3 confidence interval of PRATHER et al. (1999), which was estimated for the year 1992. Note that the MARQUART et al. (2003) estimate for 1992 (3.5 mW/m2) is outside the IPCC confidence interval.

Due to the strong decrease in the estimate for the TRADEOFF contrail RF, the new total (48 mW/m2) is smaller than the IPCC-based estimate for 2000 and marginally smaller than the IPCC value for 1992 (48.5 mW/m2). As in PRATHER et al. (1999), the total does not include the contribution from aircraft induced cirrus changes beyond linear contrails. We did not provide confidence intervals for TRADEOFF mean values of RFs, because we consider that the number of independent estimates for the individual contributions is too small to provide reliable confidence intervals.

At the bottom of Figure 1 the current level of scientific understanding is indicated, with the grades “good”, “fair” and “poor”. This is a measure independent of the magnitude of the 2/3 confidence intervals. Actually, the level of scientific understanding can be “good” while at the same time the 2/3 confidence interval is large, due to high internal variability of the process considered. The grades are, as was with IPCC (1999), based on subjective expert judgement. But contrary to IPCC (1999) we use fewer grades, only 3, as these grades are a quite crude judgement and, therefore, any finer categories would introduce more subjectivity.

5 Cirrus clouds

Apart from triggering linear contrails, aviation has the potential to change cirrus clouds in the following ways:

(1) Contrails do not always evaporate after some minutes. If the background atmosphere is sufficiently supersaturated with respect to the ice phase, they can grow to larger cirrus clouds, called contrail cirrus, which cannot be distinguished from natural cirrus clouds if their history is unknown. The formation of such contrail cirrus has been observed (SCHUMANN and WENDLING, 1990; MINNIS et al., 1998). MANNSTEIN and SCHUMANN (2005) estimated that the cover by contrail cirrus in central Europe is approximately 10 times larger than the cover by linear contrails.

(2) Aircraft directly emit particles (e.g., soot) and also precursors of volatile particles (e.g., sulphur oxides). These aerosols are eventually transformed into cloud condensation nuclei, which may trigger the formation of cirrus clouds much later than the original emission, if the background atmosphere has changed to a state allowing cloud formation (supersaturation). An observational proof of this effect is still lacking although theory allows this process. An indication of such an effect might be extracted from STRÖM and OHLSON (1998).

(3) Aircraft-induced aerosols can additionally modify the micro-physical properties of cirrus clouds, change cloud particle sizes and forms, and the number of cloud particles (KRISTENSSON et al., 2000; KÄRCHER and LOHMANN, 2003). The result of such modification may include a change in the precipitation rate, in cloud lifetime and in cloud radiative properties. A quantification of this effect is still the subject of research.
In TRADEOFF, two independent studies have been made of trends in cirrus cloudiness, both seeking to extract the trend due to air traffic (ZEREFOS et al., 2003 and STORDAL et al., 2005). The two studies were based on cloud data from ISCCP (International Satellite Cloud Climatology Project) but used different statistical approaches. STORDAL et al. (2005) calculated trends in cirrus cloud cover based on 16 years of cloud data. They correlated the trends spatially with aircraft density data to determine the changes in cirrus cloud cover due to aviation. In their study, the main emphasis was on the area covered by the METEOSAT satellite to avoid spurious trends in the ISCCP data resulting from changing satellite positions. In Europe, which is within the METEOSAT region, their analysis resulted in a trend of about 1 to 2 % per decade due to aircraft. This finding is very similar to the one derived for Europe by ZEREFOS et al. (2003), who, after removing the influences of natural phenomena (such as ENSO, OBO, NAO and tropopause variability), found an increase in cirrus cover in high air traffic areas over Europe of +1.3 % per decade, contrasting with a decrease of −0.2 % per decade in adjacent low air traffic areas. Similar positive trends in cirrus were found in other regions with high aircraft density.

STORDAL et al. (2005) extrapolated their result in time to cover a longer period of aircraft operations and the global scale, assuming the radiative efficiency of cirrus to equal that of contrails. This yielded a “mean” RF of 30 mWm$^{-2}$, associated with a large uncertainty range of 10 to 80 mWm$^{-2}$. (This range includes estimated uncertainties in the spatial correlation between trends in observed cirrus cover and aviation as well as uncertainties in the radiative impact per unit cloud cover.)

Both the studies of ZEREFOS et al. (2003) and STORDAL et al. (2005) are based primarily on correlation analyses. Such studies can provide statistical evidence of an association between aviation and observed changes in cloudiness, but do not prove causality. Coincidentally, the heaviest air traffic is found in regions where the subtropical and the subpolar jets are often found, i.e., the cloudiness in these regions is potentially sensitive to decadal natural climate variability and to anthropogenic climate change (from greenhouse gases). Therefore, we have reservations in considering the RF above as a best estimate; it rather is at least an order of magnitude estimate of the RF from aircraft-induced cirrus changes.

The new “mean” estimate (STORDAL et al., 2005) is about 25 % smaller than the IPCC upper limit given by FAHEY et al. (1999), while the new “upper bound” is about 90 % higher than the IPCC upper limit and about three times as high as the upper value given by MINNIS et al. (2004), see also Table 2. Note that both IPCC (1999) and MINNIS et al. (2004) refer to 1992, whereas the new value is for 2000, which has increased traffic over 1992.

Furthermore, good reasoning exists that RF for aviation-induced cirrus changes is positive: optically thin cirrus clouds are known to warm climate on average (HARTMANN et al., 1992), although occasionally (and regionally) RF from aviation-induced cirrus can be negative (e.g., MEERKÖTTER et al., 1999; MYHRE and STORDAL, 2001; MEYER et al., 2002; MANNSTEIN and SCHUMANN, 2005). The assumption that the radiative efficiency of cirrus equals that of contrails is highly uncertain. Nevertheless, we expect from the current knowledge that the best estimate of aviation-induced cirrus RF is somewhere between zero and an estimated upper bound. Due to this lack of knowledge it is not yet possible to add the RF for aviation-induced cirrus changes to the total aviation RF. Evidently, if the actual value was close to the “mean” value of STORDAL et al. (2005), the total RF would increase substantially, and consequently aviation’s share to the total anthropogenic RF.

6 Conclusion

The TRADEOFF project has provided an update to the aviation-induced radiative forcings (RFs). The most prominent change is that RF from (linear) contrails has been strongly reduced, by a factor of approximately three to four. The RFs from CO$_2$, O$_3$, and CH$_4$ are smaller than expected from increase in air traffic. Because of the reduced estimate of the RF from contrails, the new total for 2000 (48 mW/m$^2$) is about the same as the total provided by PRATHER et al. (1999) for the year 1992.

As in the IPCC report (PRATHER et al., 1999) the new TRADEOFF estimate does not include the contribution from aviation induced cirrus clouds. It is possible that the total aviation RF could be twice as large as the total RF given here. Potentially, the range for an estimate of RF from aviation induced cirrus clouds is much larger than the IPCC estimate. Therefore, more research is needed to reliably quantify the RF from aviation-induced changes of cirrus clouds$^1$.

It should be noted that the formation of contrails, and hence also the formation of contrail cirrus, depends on future background climate through changes in water vapour and chemical composition in a warmer atmosphere. Furthermore, the formation of contrails and the associated RF depend on cruise altitude (FICHTER et al., 2005). If this contribution of contrail cirrus to the total aviation RF is really as large as the upper estimate given in this paper, it therefore is worthwhile to investigate methods to reduce the effect by different procedures

$^1$Such research will be undertaken in, e.g., the EU FP6 Integrated Project QUANTIFY and the HGF project PAZI-2.
for selecting flight routes and altitudes, e.g., by searching routes and altitudes that minimise the formation of aircraft induced clouds (cf. SAUSEN et al., 1996).
